

- 1. Introduction.** This example applies a function to every element of a slice *concurrently*, using a fixed pool of worker goroutines, and returns the results in the original order. It exercises the Go features a literate document most wants to show off nicely: generics, goroutines, channels, *sync.WaitGroup*, and a closure.
- 2.** The program imports only the standard library and demonstrates *pmap* from *main*.

```
package main
import (
    "fmt"
    "sync"
)
⟨ The parallel-map function 3 ⟩
func main() {
    nums := []int{1, 2, 3, 4, 5, 6, 7, 8}
    squares := pmap(nums, 3, func(n int) int { return n * n })
    fmt.Println(squares)
}
```

3. The parallel map. The signature is fully generic: *pmap* maps a $[]A$ to a $[]B$ through a function f of type **func**(A) B , spreading the work over *workers* goroutines. Because each result is written to its own index, no locking of *out* is needed.

⟨The parallel-map function 3⟩ $\equiv$

```
func pmap[A, B any](in []A, workers int, f func(A) B) []B {
    out := make([]B, len(in))
    var wg sync.WaitGroup
    jobs := make(chan int)
    ⟨Start the worker goroutines 4⟩
    ⟨Dispatch one job per input index 5⟩
    wg.Wait()
    return out
}
```

This code is used in section 2.

4. Each worker pulls indices off the *jobs* channel until it is closed, computing one result per index. The **defer** guarantees the wait group is released even if f panics.

⟨Start the worker goroutines 4⟩ $\equiv$

```
for w := 0; w < workers; w++ {
    wg.Add(1)
    go func() {
        defer wg.Done()
        for i := range jobs {
            out[i] = f(in[i])
        }
    }()
}
```

This code is used in section 3.

5. The dispatcher feeds every index and then closes the channel, which is the signal for the workers to finish.

⟨Dispatch one job per input index 5⟩ $\equiv$

```
for i := range in {
    jobs ← i
}
close(jobs)
```

This code is used in section 3.
